ABSTRACT

The primary purpose of this study was to synthesize silver nanoparticles (AgNPs) utilizing chitin extracted from shrimp shell waste by simple photo-irradiation in a single-pot biosynthesis without adding any toxic chemical substances. Glucose molecules in the chitin extract act as the reducing agent, while amino acids in chitin behave like proteins and are responsible for the production of AgNPs by acting as the particle-stabilizing agent. The synthesized chitin-AgNPs were thoroughly investigated using transmission electron microscopy (TEM), Fourier-transform infrared analysis, and ultraviolet-visible absorption spectroscopy. UV-visible spectroscopy revealed a surface plasmon resonance peak at 470 nm, confirming the formation of chitin-AgNPs. FTIR data confirmed the association between chitin and AgNPs. TEM studies showed that the synthesized chitin-AgNPs have a spherical shape with particle sizes ranging from 10 to 30 nm. The prepared chitin-AgNPs exhibited intense antibacterial activity against the Gram-positive Bacillus subtilis, Staphylococcus aureus, Gram-negative Pseudomonas aeruginosa, and Escherichia coli, as well as antifungal efficacy against Aspergillus niger. Reactive oxygen species and live and dead cell assays were performed to examine the chitin-AgNPs and the results were further found to be interesting and positive. The assays revealed that the prepared chitin-AgNPs exhibited significant antimicrobial potential against B. subtilis and A. niger, with a zone of inhibition measuring approximately 6.2 mm and 30 mm, respectively. The effects of the chitin-AgNPs were compared to those of commercial agents, such as ciprofloxacin (6.0 mm) and fluconazole (25 mm). Consequently, the chitin-AgNPs developed through a greener approach show promising potential as sustainable materials for antibacterial and antifungal activities.

ARTICLE HIGHLIGHTS

● The chitin-AgNPs were synthesized through photo-irradiation reaction.
● The properties of the prepared chitin-AgNPs were studied using TEM, UV-Vis, and FT-IR spectroscopy.
● The prepared chitin-AgNPs showed superior antimicrobial activity (antibacterial and antifungal) than the commercial agents (ciprofloxacin and fluconazole).

1. INTRODUCTION

Silver’s antimicrobial properties have been recognized for a long time, dating back to the era of Hippocrates (460 BC) who wrote about its role in wound healing. In the Phoenician kingdom, silver vessels were employed for water purification, further highlighting its beneficial properties [1-3]. Over the years, metallic silver, silver nitrate, and silver sulfadiazine have been employed in the treatment of wounds, burns, and various infections. Silver was particularly prevalent in wound healing during the early to mid-twentieth century. However, the advent of potent antibiotics like penicillin led to a decline in the use of silver and other non-antibiotic therapies. The emergence of antibiotic-resistant bacteria has renewed interest in alternative solutions such as silver [4]. Among various materials, nanoscale metallic particles have gained prominence. Silver nanoparticles (AgNPs), in particular, have shown remarkable effectiveness as antimicrobial agents due to their high surface area-to-volume ratio [5]. Several methods, including physical, chemical, and physicochemical processes, can be employed to produce AgNPs [6,7]. However, the physical method, although fast and requiring fewer chemicals, has drawbacks such as high energy consumption, expensive equipment, low yields, and the production of highly polydisperse samples [8,9].

To utilize the chemical method for synthesizing AgNPs, certain components are necessary. This includes a precursor metal serving as
a reduction agent and as a stabilizing or capping agent [10,11]. Various reducing agents such as citrate, ascorbate, sodium borohydride, dimethylformamide, and polyol process, along with capping agents such as poly(methyl methacrylate), poly(ethylene glycol), poly(methacrylic acid), poly(vinyl alcohol), and poly(vinylpyrrolidone) are commonly employed in chemical synthesis [10,12]. However, using chemical compounds in nanoparticle synthesis poses challenges as they tend to bind to the nanoparticle surface, making it difficult to achieve high-purity nanoparticles. Therefore, there is a need for cost-effective and environmentally friendly methods to synthesize AgNPs, avoiding the use of hazardous chemicals and solvents for various biomedical applications [13,14]. Green chemical routes using extracts from natural resources such as mango, grape, pomegranate, pineapple, ginger, imperial crown leaves, moringa oleifera (drumstick tree), and citrus macroptera (wild orange), as well as chitin and chitosan, have shown promise in serving as both reducing and stabilizing agents, as evident from the literature [15-19].

Globally, approximately 6–8 million tons of waste lobster, crab, and shrimp shells are generated yearly, with Southeast Asia alone producing around 1.5 million tons of shell waste. In many developing countries, these waste shells are typically discarded in the sea or landfills [20]. However, in developed countries such as Australia, waste disposal can be costly, amounting to approximately $150 per ton [20]. Unfortunately, the potential value of such waste shells in the chemical sector has been overlooked. Scientists and industries are now focusing on finding sustainable ways to utilize crustacean shells. Chitin, a biologically compatible and biodegradable polymer, is extracted from these shells [21]. After deproteination, demineralization, and decoloration processes, chitosan is obtained from chitin, which is more biocompatible and biodegradable [22,23]. Chitin one of the most abundant biopolymers in nature after cellulose finds applications in various fields such as biocatalysts, biomedicine, the food industry, agriculture, and the pharmaceutical industry [24]. Its solubility in aqueous acid solutions and the ease with which it can be processed into different forms such as nanoparticles, microparticle films, sponges, hydrogels, and threads make chitin a versatile material [25-27]. Due to its biodegradability, biocompatibility, and wound-healing properties, chitin holds special significance in the pharmaceutical industry [21,28-30]. This study focused on synthesizing chitin-AgNPs using chitin derived from crustacean waste (shrimp shells) through a green synthetic methodology. The chitin-AgNPs were synthesized using a simple photoreduction method without heat treatment or harsh conditions. The synthesized chitin-AgNPs were extensively characterized using various analytical techniques and their antimicrobial activities, specifically antibacterial (Gram-positive Bacillus subtilis, Staphylococcus aureus and Gram-negative Pseudomonas aeruginosa, Escherichia coli) and antifungal (Aspergillus niger) activities, were investigated.

2. MATERIALS AND METHODS

2.1. Chemicals

Silver nitrate (AgNO₃), potato dextrose agar, Mueller-Hinton broth (MHB), ciprofloxacin, and fluconazole (FLC) were obtained from Sisco research laboratories, India. Phosphoric acid and sulfuric acid were purchased from Hychem Laboratories, India. DCFH-DA (2',7'-dichlorofluorescein diacetate, 35845–5G) was obtained from Sigma Aldrich, India. The Live/dead Bac Light bacterial viability kit (L7012) was procured from Invitrogen, Korea. All the chemicals and reagents used were of analytical reagent grade and used as received without any additional purification. Deionized water (DI) was used for the preparation of all experimental solutions.

2.2. Extraction of Chitin from Shells

Shrimp shells were obtained from the local market near GITAM University, India. The collected shells were thoroughly washed with deionized (DI) water. After washing, the shells were air-dried overnight and then ground using a mortar and pestle. The resulting powder was weighed to approximately 2 g and mixed with 100 mL of 3% v/v phosphoric acid. The mixture was stirred on a magnetic stirrer at room temperature (RT) for 12 h to facilitate demineralization. The chitin extract was separated from the solid residue by filtration using Whatman No.1 filter paper. The filtrate was further subjected to centrifugation at 4000 rpm for 20 min. The supernatant, containing the chitin extract, was collected and stored at 4°C for future use.

2.3. Synthesis of Chitin-AgNPs

An initial preparation of AgNO₃ solution (0.1 mM) was made and added to the chitin extract in a volume ratio 1:2 (AgNO₃ : chitin extract). The resulting solution was placed in a closed chamber on a magnetic stirrer and exposed to light from a 60 W incandescent bulb (Philips) at RT for 120 min. This setup allowed for the production of chitin-AgNPs. The color of the solution changed from colorless to brown, indicating the formation of chitin-AgNPs through the reduction of silver ions. The synthesized chitin-AgNPs were then stored at 4°C to further analysis and investigation of their potential biomedical applications.

2.4. Characterization Techniques

The optical properties of chitin-AgNPs were investigated using a UV–visible spectrophotometer (UV 1800, Shimadzu, Japan). Fourier-transform infrared analysis (FT-IR) to examine the functional groups of chitin-AgNPs was conducted using a Bruker ATR-FTIR spectrometer in ATR mode (USA). Transmission electron microscopy (TEM) was performed using a JEOL-2100F microscope (USA) operating at 200 kV for size determination analysis of particles. The chitin-AgNP solution was deposited onto carbon-coated copper grids for TEM imaging. Fluorescent images of chitin-AgNPs were captured using a Nikon Invitrogen fluorescence microscope (Eclipse 80i, Japan). Image analysis of chitin-AgNPs was conducted using Origin 9 and Image J software [31,32]. All experiments were performed in triplicates to ensure the reliability and reproducibility of the results.

2.5. Antibacterial Activity

The agar-well diffusion method [33] was employed to evaluate the antibacterial properties of the chitin-AgNPs against various bacterial strains, including S. aureus (ATCC 6538 KCCP 60034), B. subtilis (ATCC 23875) Gram-positive, E. coli (C600), and P. aeruginosa (ATCC 15442) Gram-negative are obtained from Korean Culture Collection of Probiotics KCCP (50037). Ciprofloxacin (1 mg/mL, antibiotic) was used as a positive reference. The bacterial strains were cultured in sterilized MHB and incubated at 37°C for 18 h. The MHB medium containing bacterial inoculums was aseptically transferred to Petri plates. Prepared wells with a diameter of 8 mm received additions of 25, 50, 75, and 100 µL (1 mg/mL) of chitin-AgNPs corresponding to the respective wells. Wells with a diameter of 8 mm were prepared, and 25, 50, 75, and 100 µL (1 mg/mL) of chitin-AgNPs were added to the respective wells. The plates were then incubated at 37°C overnight. After incubation, the diameter of the inhibition zone formed around each well was measured in millimeters to assess the antibacterial
activity. To ensure the reliability and reproducibility of the results, all experiments were performed in triplicates.

2.6. Antifungal Activity
The agar-well diffusion method was employed to evaluate the antifungal properties of the chitin-AgNPs against A. niger (ATCC 11414) are obtained from Korean Culture Collection of Probiotics KCCP (50037). As a positive reference, FLC, an antifungal agent, was used at a concentration of 1 mg/mL. Potato dextrose agar slants were prepared and incubated at 37°C for 24 h to investigate the antifungal activity. The prepared medium was then poured into Petri plates and allowed to solidify under aseptic conditions. A sterile cotton swab was dipped into the fungal strain suspension and used to inoculate the agar surface. The inoculum was spread evenly across the entire agar surface by streaking in three directions with the cotton swab. Prepared wells with a diameter of 8 mm received additions of 25, 50, 75, and 100 µL (1 mg/mL) of chitin-AgNPs corresponding to the respective wells. The plates were incubated at 37°C for 4 days. After incubation, the diameter of the inhibitory zones formed around each well was measured in millimeters to evaluate the antifungal activity. These experiments were conducted in triplicates to ensure reliable results.

2.7. Live/Dead Cell Viability Assay
Bacterial cell viability of E. coli and B. subtilis was assessed using a live and dead staining assay after treatment with chitin-AgNPs. The bacterial cells were incubated for 60 min following treatment with a live and dead cell staining solution. Subsequently, the untreated and treated cells of E. coli and B. subtilis, along with the control, were examined using a fluorescence microscope. Images were captured using Nikon’s live cell capture software.

2.8. Reactive Oxygen Species (ROS) Assay
DCFH-DA (2′,7′-dichlorodihydrofluorescein diacetate) was employed to assess the production of ROS in E. coli and B. subtilis following treatment with chitin-AgNPs (25, 50, 75, and 100 µL). The excitation and emission wavelengths used were 480 nm and 520 nm, respectively. Sixteen-well plates were used, and incremental amounts of chitin-AgNPs (25, 50, 75, and 100 µL) were added to each well. The plates were then incubated separately with 1 mL of E. coli and B. subtilis for 6 h at 37°C. The bacterial suspension was incubated in the dark for 30 min after adding 100 M DCFH-DA. Subsequently, 10 µL of each aliquot was placed on a glass slide, covered with a cover slip, and studied using a fluorescence microscope with a ×100 objective lens and a green filter.

2.9. Statistical Analysis
All the complete data shown in this research work were the mean and standard deviation (±SD) of three individual experiments. Three-factor analysis of variance, ANOVA, was performed, and the statistical significance between values was accepted. The values were presented as the mean.

3. RESULTS AND DISCUSSION
In this work, chitin was obtained from crustacean wastes by a green synthetic approach. Later, the obtained bio-based eco-friendly chitin biopolymer was used as stabilizing and reducing agent for the preparation of AgNPs by photoirradiation reaction as shown in Figure 1. The prepared chitin-AgNPs were thoroughly investigated using TEM, FT-IR, and ultraviolet-visible absorption spectroscopy. Further, chitin-AgNPs were used to study the antifungal and antibacterial effect against various microorganisms and compared with reference materials.

3.1. Optical Properties
The brown color of chitin-AgNPs results from the surface plasmon resonance phenomenon surface plasmon resonance (SPR), which occurs due to the collective oscillation of electrons on the metal surface. This phenomenon is characterized by a distinct absorption band in the 400–500 nm range. The absorption spectra of chitin-AgNPs exhibit a broad absorption band at 450–480 nm [Figure 2a and b], which indicates SPR. The broadening of the band suggests the presence of polydispersity in the chitin-AgNPs. The optimal ratio of AgNO3 to chitin was observed as 1:2 v/v from Figure 2a. Then, the 1:2 v/v mixture of AgNO3 and chitin solution was exposed to photo-irradiation for different time interval. The optimal formation of chitin-AgNPs was observed when a mixture of AgNO3 and chitin solution subjected to photoirradiation for 120 min.

3.2. FT-IR Studies
The FT-IR analysis was conducted to investigate the chemical functionalities of the synthesized chitin-AgNPs [Figure 3]. The FT-IR spectra of chitin-AgNPs exhibit prominent peaks at 3457, 1640, 1182, 1006, and 660 cm⁻¹. The peak at 3457 cm⁻¹ corresponds to the stretching vibrations of alcohol (–OH) groups, while the peak at 1640 cm⁻¹ is attributed to the amide I band. The peaks at 1182, 1006, and 660 cm⁻¹ can be attributed to the stretching vibrations of the (C-O) bonds in the saccharide structure of chitin. In addition, peaks at 2884, 2963, and 1393 cm⁻¹ are observed, which corresponds to the symmetric stretching of -CH3 groups, the asymmetric stretching of -CH2 groups, and -CH...
bending vibrations, respectively [34]. These results confirm the successful modification of chitin with the newly formed chitin-AgNPs.

3.3. Morphological Studies

The morphology and dispersion ability of the synthesized chitin-AgNPs were examined using low-resolution TEM and HRTEM analysis [Figure 4]. The TEM images of the as-prepared chitin-AgNPs revealed a spherical morphology with uniform dispersion [Figure 4a-e]. By analyzing the TEM images using Image J software, the average particle size of chitin-AgNPs was determined to be in the range of 10–30 nm. The particle size distribution of the chitin-AgNPs, depicted in the histogram [Figure 4f], was calculated using Origin software (Gaussian distribution).

3.4. Antibacterial Activity of Chitin-AgNPs

The antibacterial effect of chitin-AgNPs was evaluated using the well-diffusion method against Gram-positive bacteria *S. aureus* and *B. subtilis*, as well as Gram-negative bacteria *E. coli* and *P. aeruginosa* [Figure 5a-e]. The results showed that chitin-AgNPs exhibited the highest zone of inhibition against *B. subtilis* (6.2 mm) compared to *E. coli* (3.3 mm) when added at a concentration of 100 µL. The zone of inhibition increased incrementally with the addition of chitin-AgNPs (25, 50, 75, and 100 µL), with the highest inhibition observed at 100 µL. The antibacterial activity of chitin-AgNPs at 100 µL was comparable to that of ciprofloxacin (1 mg/mL), a well-known antibacterial agent, for most of the strains tested, and it performed better than the control in the case of *B. subtilis* [Table 1]. The observed antibacterial activity of chitin-AgNPs is consistent with previous studies where AgNPs demonstrated size-dependent toxicity on microbial species, with smaller nanoparticles showing decreased toxicity [35]. The size of chitin-AgNPs ranges from 10 to 30 nm, indicating their effectiveness in exerting bactericidal and fungicidal effects on various microbial species, even at low concentrations. In a related study, Xinjing Wei *et al.* [36] reported the antibacterial effect of AgNPs prepared using a green approach against *E. coli* and *S. aureus*. This work builds upon using chitin extracted from shrimp shell waste to achieve antibacterial effects against four different bacterial strains. The generation of ROS within bacterial cells can be attributed to the observed antibacterial activity of chitin-AgNPs. The rigid plasma membrane of Gram-positive bacteria is more susceptible to membrane damage, while the flexible membrane of Gram-negative bacteria allows for external damage. However, the synthesized chitin-AgNPs demonstrated similar effects on both species under comparable conditions.

3.5. Antifungal Activity of Chitin-AgNPs

The antifungal activities of chitin-AgNPs were analyzed by well-diffusion method using chitin-AgNPs against *A. niger* and presented in Figure 5f-j. Similar to the antibacterial effect, chitin-AgNPs have shown an incremental increase in the zone of inhibition under
incremental addition (25, 50, 75, and 100 µL) of chitin-AgNPs with the highest inhibition at 100 µL. Antifungal activity of chitin-AgNPs (100 µL) was found to have an inhibition region of ~30 mm which performed better than the well-known antifungal agent, FLC (1 mg/mL), which has an inhibition region of ~25 mm [Table 1]. The antibacterial and antifungal activities of chitin-AgNPs increased as the amount of AgNPs in the chitin matrix.

3.6. Live/Dead Cell Viability Assay

The capability of chitin-AgNPs on E. coli and B. subtilis cells has been examined using the live and dead assay to observe the membrane damage in these cell lines. In this study, for differentiation in the color green and red the E. coli and B. subtilis cells were stained by SYTO 9 and propidium iodide, respectively. The appearance of green color fluorescence in the cells confirms that the intact membrane was making them alive, and the formation of red color fluorescence denotes a damaged cell membrane vis a vis dead cell. E. coli cells (control) display a characteristic intact morphology with intense green fluorescence [Figure 6a]. The chitin-AgNPs treated E. coli cells with incremental addition (25, 50, 75, and 100 µL) display a decrease in the number of green fluorescent cells and an increase in the cells with red fluorescence [Figure 6b-e]. Similarly, the B. subtilis (control) exhibits a distinctive intact morphology with intense green

*Ciprofloxacin for bacterial strains and fluconazole for fungal strain were used as controls. ±SD values of this research work derived from the mean of data from three individual experiments, S. aureus: Staphylococcus aureus, P. aeruginosa: Pseudomonas aeruginosa, A. niger: Aspergillus niger, DIZ: Diameter of inhibition zone.
fluorescence [Figure 6f]. The chitin-AgNPs treated *B. subtilis* with incremental addition (25, 50, 75, and 100 µL) displays a decrease in the number of green fluorescent cells and there is an increase in the cells with red fluorescence [Figure 6g-j]. This effectively confirms that the synthesized chitin-AgNPs have a significant bactericidal effect on both *E. coli* and *B. subtilis*, showing excellent antimicrobial efficiency.

3.7. ROS Assay

The main reason for cell damage in antibacterial activity is oxidative stress created by chitin/AgNPs. The ROS assay studies were performed on *E. coli* and *B. subtilis* by treating them with incremental addition of chitin-AgNPs (25, 50, 75, and 100 µL) incubation for 6 h and stained with DCFH-DA (2′,7′-dichlorofluorescein diacetate) for the determination of oxidative stress facilitated by chitin/AgNPs. As the amount of addition of chitin-AgNPs is increased, a significant increase in oxidative stress was noticed in both *E. coli* and *B. subtilis*, which is evident from the increase in green fluorescence [Figure 7, Supporting Information Table S1, Figures S1 and S2]. Compared with untreated cells, cells treated with chitin-AgNPs showed an increase in ROS production, leading to cell death in both bacterial strains. To discuss the antibacterial activity of chitin/AgNPs, the possible mechanism of action has been explored through ROS assay, as shown in Figure 8 (Figure was drawn using “ChemBiodraw Ultra 14.0” software tool). The effective antimicrobial activity of AgNPs is owing to their capability of generating ROS and free radical species such as H$_2$O$_2$, O$_2^-$, HO$_2^-$, HOCI, and singlet oxygen [37]. The antibacterial ability of AgNPs is correlated with ROS and free radicals’ production and subsequent rise in oxidative stress in cells [38,39]. The ROS generation in the bacterial cells may have been attributed to the degradation of bacterial cellular constituents, including DNA, lipids, and proteins. It is believed that the cellular internalization of H$_2$O$_2$ may have played a key role in the degradation of cellular constituents by losing the integrity of bacterial cells. Herein, the chitin-AgNPs may have induced the exposure of radicals, i.e., O$_2^-$ and HO$_2^-$ on the bacterial cells, which triggers the degradation of bacterial cellular constituents. A higher concentration of Ag$^+$ ions is probable to cause a rise in cellular oxidative stress. Hence, the antibacterial activity is mainly based on the potential involvement of ROS. Increased ROS level can increase the oxidative stress in bacterial cells, which lead to effective bacterial killing [33,40,41]. The above mechanism strongly correlated with the ROS assay results [Table S1, Figures S1 and S2].

Shrimp shell waste is produced in massive quantities from the shrimp processing sectors worldwide, and it is mostly disposed into landfill or the sea, resulting in extreme environmental pollution. Waste Crustacean shell is among the major resources exploited for producing protein, chitin, and calcium carbonate. Crustacean shells contain 15–40% chitin 20–50%, calcium carbonate, and 20–40% protein. Protein is used as animal feed. As livestock reproduction increases promptly, crustacean waste shells from southeast Asia may possibly be converted into rich protein animal feed with a market value of >$100 million. Calcium carbonate has widespread applications in the agricultural, pharmaceutical, paper, and construction sectors. At present, it comes from limestone and marble. The cheapest coarse particles were produced from crustacean waste shells from Asia with a market value of up to $45 million. Another important material obtained from the crustacean shell is chitin. Chitin is the 2nd highest abundant

biopolymer on the globe after the cellulose biopolymer. Currently, chitin and chitosan are employed in various industrial applications, such as textile, cosmetics, biomedicine, and water treatment [20,42,43]. Recently, chitin is investigated as a natural cationic biopolymer due to its exceptional biocompatibility, non-toxicity, biodegradability, antimicrobial ability, etc. In this work, chitin was obtained from crustacean wastes by a green synthetic approach. Later, the obtained bio-based eco-friendly chitin biopolymer was used as a stabilizing and reducing agent for preparation of AgNPs by photoirradiation reaction. The developed chitin/AgNPs showed good antifungal and antibacterial effect against various microorganisms. Shrimp shell waste is not only used for the production of chitin also it is used as a probable raw material for the production of bioethanol and biodiesel [43]. Further shrimp shell waste was used as an efficient adsorbent for removal of metal from polluted water and explored as an antioxidant, and neuroprotective activities [44,45]. Still, there is lots of scope to utilize the shrimp shell waste in different fields. In future, we plan to use shrimp shell waste in diverse applications, including as a catalyst, adsorbent, hydrogel material for bioelectronics, etc.

4. CONCLUSION

In this study, we successfully synthesized chitin-AgNPs using a simple and environmentally friendly chemical approach, avoiding the use of hazardous chemicals. The chitin extract derived from crustacean shells served as an effective reducing, protecting/capping, and stabilizing agent. The UV-visible absorption studies demonstrated a distinct and intense SPR peak at 470 nm, indicating the successful formation of chitin-AgNPs. TEM analysis revealed that the synthesized chitin-AgNPs exhibited a particle size range of 10–30 nm and displayed good dispersibility and stability in water. Furthermore, the synthesized chitin-AgNPs exhibited remarkable biocidal activity against the Gram-positive bacterium B. subtilis and displayed antifungal effects against A. niger, surpassing the efficacy of commercially available drugs. These findings position chitin-AgNPs as a promising alternative in the field of antimicrobial agents. Mechanistic studies provided insights into the potential cell-killing mechanism of AgNPs in E. coli and B. subtilis. Overall, the environmentally friendly synthesis of chitin-AgNPs highlights their potential for utilization as effective antimicrobial agents in the near future.
